The existence of a SM-like Higgs constrains all directions of exploration.
Motivational Issues

- There is a rather SM-like Higgs boson at $m_h = 125$ GeV.
- There is no sign of supersymmetry.
- There is an increasingly convincing excess of di-photon events at $m_{\gamma\gamma} \sim 750$ GeV.
- Maybe it is time to look at alternative models in which there is no hierarchy problem and the two observed states are present with the observed cross sections and characteristics.

The Randall Sundrum two-brane model fits the bill. In this model one places the SM, including its Higgs sector, into the context of a 5th (extra) dimension.

Two options:
1. The 750 GeV state is the first excited KK mode of the graviton with mass $m_{KK}^1$.
2. The 750 GeV state is mainly (but not entirely) the radion, $\phi$, of the model, where the radion is the quantum fluctuation associated with the separation of the two branes.
Two more options: do SM particles propagate in the bulk or are they localized on the IR (TeV) brane?

1. Localize on the brane:

   The gluon (and other SM particles) do not propagate in the bulk and hence there are no excited states of the gluon (or any other SM particle). This means that there are no collider bounds on the excited states (KK modes) of the SM particles since they don’t exist.

![Figure 1: The two RS brane pictures.](image)

2. Allow the gauge bosons and possibly other SM particles to propagate in the bulk.

   The excited state of immediate importance is the first excitation of the gluon with mass $m_g^1$. In this case, collider data already imply $m_g^1 > 3$ TeV.
• Option 1 (KK graviton) has been considered, for example, recently in arXiv:1602.02793.

  – The model has basically one parameter $\Lambda$ that determines everything once $m_{1}^{KK} = 750 \text{ GeV}$ is imposed.
  – $\Lambda \sim 60 \text{ TeV}$ in order to fit the di-photon signal.
  – But, other final states are predicted to have very significant rates. The most worrisome are the $e^+e^-, \mu^+\mu^-$ final states, predictions for which are only very marginally consistent with existing 8 TeV limits (and only at 95% CL). Predictions for these final states at 13 TeV will be easily excluded as Run2 continues.

• Option 2 (Radion) is our choice: arXiv:1512.05771

  – We claim the most (and maybe only) natural interpretation of the 750 GeV state is a radion. It really works very well.
  – In particular, we will see that if the gluon propagates in the bulk then the KK graviton cannot be as light as 750 GeV.

Although dark matter is not present in the simplest incarnation of the RS Higgs-radion approach, it is easily added, for example by adding an extra (stable) singlet to the simplest one-doublet Higgs sector of the model.
Basics of the Model

• RS metric:

\[ ds^2 = e^{-2k_b_0|y|} \eta_{\mu\nu}dx^\mu dx^\nu - b_0^2 dy^2, \]  

(1)

– \( k \) is the curvature of the 5D geometry,
– \( b_0 \) is a length parameter for the 5th dimension, and \(-1/2 \leq y \leq 1/2\).
– \( \frac{1}{2} k b_0 \approx 35 \), for the RS model to constitute a full solution to the hierarchy problem.
– The fluctuation of the 55-component associated with \( b_0 \) is the radion, \( \phi_0(x) \).
  The VEV of \( \phi_0 \) is denoted \( \Lambda_\phi \).

• Critical parameter relations:

– \( m_1^{KK} = x_1^{KK} k \frac{\Lambda_\phi}{M_{Pl} \sqrt{6}} \), where \( x_1^{KK} = 3.83 \) (Note: \( x_2^{KK} \approx 7 \)).
– \( m_1^g = x_1^g k \frac{\Lambda_\phi}{M_{Pl} \sqrt{6}} \sim \frac{k}{M_{Pl}} \Lambda_\phi \), where \( x_1^g = 2.45 \), implying \( m_1^{KK} \approx 1.55 m_1^g \).
– Collider data limit of \( m_1^g > 3 \) TeV, implies \( m_1^{KK} > 4.6 \) TeV.
  This can be avoided at the price of including brane kinetic terms for gauge fields and gravity localized on the “visible” (IR) brane. Without this, only the radion interpretation of the 750 GeV resonance is viable. \( \Rightarrow \) The natural choice.
For the radion interpretation of the 750 GeV state it is critical to include a Higgs-gravity coupling, $\xi R_4 H^\dagger H$ (localized on the IR brane), where $\xi$ is a dimensionless parameter and $R_4$ is the four-dimensional (4D) Ricci scalar coming from the induced metric on the IR brane.

This results in the following 4D effective Lagrangian for the scalar sector,

$$\mathcal{L}_{\text{eff}} = \frac{1}{2} (\partial_\mu \phi_0)^2 - \frac{1}{2} m_{\phi_0}^2 \phi_0^2 - 6 \xi \Omega \Box \Omega H^\dagger H + |D_\mu H|^2 - \Omega^4 V(H), \quad (2)$$

where $\phi_0$ is the (unmixed) radion field and $m_{\phi_0}$ its bare mass. Above, $\Omega(\phi_0) \equiv 1 - \ell \phi_0 / v_0$, where

$$\ell \equiv \frac{v_0}{\Lambda_\phi} \quad (3)$$

with $v_0 = 246$ GeV and $\Lambda_\phi \equiv \sqrt{6} M_{\text{Pl}} e^{-k b_0 / 2}$ is the vacuum expectation value (VEV) of the radion field.

As we will show below, phenomenological constraints make it difficult to accommodate $\Lambda_\phi \lesssim 1.5$ TeV, implying that $\ell$ is limited to $\ell \lesssim 1/6$. 

At the quadratic level, the above yields

\[
L_{\text{eff}}^{(2)} = -\frac{1}{2} (1 + 6\xi\ell^2) \phi_0 \Box \phi_0 - \frac{1}{2} m_{\phi_0}^2 \phi_0^2 + 6\xi\ell h_0 \Box \phi_0 - \frac{1}{2} h_0 \Box h_0 - \frac{1}{2} m_{h_0}^2 h_0^2,
\]

where \( h_0 \) is the neutral scalar of the Higgs doublet \( H \), and \( m_{h_0} \equiv \sqrt{2} \lambda v_0 \) is the bare Higgs mass. In the above Lagrangian, the \( \xi \) term that mixes the Higgs and the radion can be removed by rotating the scalar fields into the mass eigenstate basis,

\[
\begin{pmatrix}
\phi_0 \\
h_0
\end{pmatrix}
= \begin{pmatrix}
-a & -b \\
c & d
\end{pmatrix}
\begin{pmatrix}
\phi \\
h
\end{pmatrix},
\]

where \( a = -\cos \theta / Z \), \( b = \sin \theta / Z \), \( c = \sin \theta + t \cos \theta \) and \( d = \cos \theta - t \sin \theta \), with \( t \equiv 6\xi\ell / Z \), \( Z^2 \equiv 1 + 6\xi\ell^2(1 - 6\xi) \) and

\[
\tan 2\theta = \frac{12\xi\ell Z m_{h_0}^2}{m_{\phi_0}^2 - m_{h_0}^2 (Z^2 - 36\xi^2\ell^2)}.
\]

Given that \( \ell \lesssim 1/6 \) for the \( \Lambda_\phi \gtrsim 1.5 \) TeV range of interest and that we will focus on \( \xi \) values near the \( \xi = 1/6 \) conformal limit, it is legitimate to expand Eq. (6) in
powers of $\ell$ and express the result in terms of the physical mass parameters, $m_h$ and $m_\phi$:

$$\tan 2\theta = \frac{12\xi \ell m_h^2}{Z(m_\phi^2 + m_h^2 - 2m_{h0}^2)} \approx 12\xi \ell \left(\frac{m_h}{m_\phi}\right)^2 \left[1 - 3\xi(1 - 6\xi)\ell^2\right] + \cdots,$$

where the ellipsis stands for terms which are quite small for $m_\phi = 750$ GeV and $\Lambda_\phi \gtrsim 1.5$ TeV. For $\xi = 1/6$ and $\ell \lesssim 1/6$ one obtains $\theta \simeq \ell (m_h/m_\phi)^2 \lesssim (1/6)^3$.

- IMPORTANT: relation between $m_{1g}^g$ (1st gluonic KK excitation), $\langle \phi_0 \rangle = \Lambda_\phi$ and the curvature ratio $k/M_{Pl}$:

$$m_{1g}^g = \frac{x_{1g}^g}{\sqrt{6} M_{Pl}} \frac{k}{\Lambda_\phi} \simeq \frac{k}{M_{Pl}} \Lambda_\phi,$$

where $x_{1g}^g \simeq 2.45$ is the 1st zero of an appropriate Bessel function. This relation is depicted in the following figure.
Figure 2: Correlation between $m_1^g$ and $k/M_{P1}$ for different contours of $\Lambda_\phi$ (in TeV). The region below $m_1^g = 3$ TeV (dashed-red line) is excluded by the EWPO and direct collider limits. We will need $\Lambda_\phi \lesssim 2.5$ TeV which implies $k/M_{P1} \gtrsim 1$. $\Lambda_\phi = 1.5$ TeV requires $k/M_{P1} = 2$ ($3$) for $m_1^g = 3$ TeV (5 TeV). Originally, $k/M_{P1}$ values $< 1$ seemed best motivated; however, more recently $k/M_{P1}$ values $> 1$ are deemed equally plausible, with $k/M_{P1}$ as large as 3 possible without invoking quantum gravity related issues.
• Particle “locations”:

- The Higgs, $t$ and $b$ will be placed on the IR brane $\Rightarrow$ heavy $t$ natural.
- We want to place all gauge bosons in the bulk.
  * In the case of the $g$ and $\gamma$ this is required in order to have enhanced $gg$ and $\gamma\gamma$ couplings.
  * But, if the $W$ and $Z$ are in the bulk, EWPO constraints naively imply $m_1^g > 10$ TeV, which implies too large a value for $\Lambda$ to obtain the observed di-photon cross-section.
  * However, by introducing a local custodial symmetry of $SU(2)_L \times SU(2)_R \times U(1)_X$ (where the $SU(2)_R \times U(1)_X$ fields are broken to $U(1)_Y$ on the UV brane, such that $Y = T^3_R + X$) then it is possible for $m_1^g$ to have mass as low as $m_1^g \sim 3$ to 5 TeV.

This is required for the model to have low enough $\Lambda$, i.e. $\Lambda \lesssim 2.5$ TeV (see Fig. 2) so as to reproduce the observed di-photon cross-section.

• Couplings:

Radion couplings are in Fig. 3. Not shown: the very complicated form of $g_{\phi hh}$. 
Figure 3: Selected radion couplings. The $4\pi/(\alpha_s k b_0)$ for the $\gamma\gamma$, $gg$ couplings and the $\kappa_V$ terms and non-SM tensor structures in the $WW$ and $ZZ$ vertices are all due to the vector bosons being present in the bulk.
Notes:

- The coupling of the radion to the trace of the energy momentum tensor implies that the $\phi\gamma\gamma$ and $\phi gg$ couplings have extra “anomalous” contributions with magnitude determined by the respective $\beta$ functions.

- In addition, the $g$ and $\gamma$ couplings have $\frac{4\pi}{\alpha_s k b_0}$ and $\frac{4\pi}{\alpha k b_0}$ terms, respectively, added to the anomalous contributions.

In the $\gamma\gamma$ case, the small size of $\alpha$ implies that this piece dominates the anomaly piece. Indeed, without this extra “bulk” piece the $\gamma\gamma$ signal rate could not be as large as that observed.

- As discussed below, the other pieces (i.e. those proportional to $g_\phi$) will be small for the choices of $\xi \sim 0.162$ of relevance, where the $t\bar{t}$, $b\bar{b}$ and $hh$ couplings are nearly zero.

  ⇒ at $\xi = 0.162$, $gg$ will dominate and $\gamma\gamma$ will be big.

• Coincident “zeroes”.

  1. For the $t\bar{t}$, $b\bar{b}$ the coupling strength is:

  $$g_\phi = \ell \left[ 6\xi \left( \frac{m_h}{m_\phi} \right)^2 + 6\xi - 1 \right] \approx \ell \left( \frac{37}{6} \xi - 1 \right)$$  \hspace{1cm} (9)
One finds $g_\phi = 0$ for $\xi \simeq 0.162162$. At this point the $gg$ and $\gamma\gamma$ couplings come entirely from the anomalous+bulk contributions.

2. For the $hh$ coupling one finds:

$$
\frac{g_{\phi hh} \Lambda_\phi}{m_\phi^2} = (1 - 6\xi) + \frac{2m_h^2}{m_\phi^2}(1 - 9\xi) - 18\xi \left(\frac{m_h^2}{m_\phi^2}\right)^2 = \frac{19}{18}(1 - 6.17105\xi) \tag{10}
$$

Numerically, $g_{\phi hh}$ vanishes for $\xi = 0.162047$, i.e. very close to the value for which $g_\phi$ vanishes.

3. For the $VV = WW, ZZ$ couplings, the external $\eta_V = g_\phi - g_\phi^r \kappa_V$ values are:

$$
\eta_V = g_\phi - g_\phi^r \kappa_V \simeq \ell \left[ \kappa_V + 6\xi \left(\frac{m_h}{m_\phi}\right)^2 + 6\xi - 1 \right], \tag{11}
$$

where $\kappa_V = \frac{3kb_0m_V^2}{2\Lambda_\phi^2(k/M_{Pl})^2} \simeq \frac{105m_V^2}{m_1^g}$ for $kb_0/2 \sim 35$ using the very good approximation $\Lambda_\phi(k/M_{Pl}) = m_1^g$, see Eq. (8).

For $m_1^g = 3$ TeV, one finds $\kappa_W = 0.0761$ and $\kappa_Z = 0.0981$. As a result, $\eta_V$ vanishes at $\xi = 0.150, 0.146$ in the $W$, $Z$ cases, respectively. Of course,
the zeroes shift closer to the $\xi = 0.162$ point for $m_1^g = 5$ TeV, occurring at $\xi = 0.158, 0.157$, respectively.

4. Note that the $g_\phi$, $g_{\phi h h}$ and non-$\kappa_V$ term zeroes all approach the conformal point of $\xi = 1/6$ as $m_h/m_\phi \rightarrow 0$.

- **Resulting di-photon signal:**

![Graph](image.png)

Figure 4: Left: $\sigma(gg \rightarrow \phi \rightarrow \gamma\gamma)$ as a function of $\xi$ for $m_h = 125$ GeV, $m_\phi = 750$ GeV and $m_1^g = 3$ TeV with different choices of $\Lambda_\phi$ as indicated by the coloration. Right: $\sigma(gg \rightarrow \phi \rightarrow \gamma\gamma)$ for different values of $m_1^g$ and $\Lambda_\phi$. ATLAS and CMS results are the light-green and yellow bands. Need $\Lambda_\phi = 1.5$ TeV to hit “central” values, which, in turn, is only possible if $m_1^g = 3$ TeV given $k/M_{Pl} \leq 3$. Maximal $\gamma\gamma$ rate shifts from $\xi = 0.15$ to $\xi = 0.16$ for $m_1^g = 3$ TeV $\rightarrow 5$ TeV.
Figure 5: Branching ratios for the $\phi$, illustrating the shift of the $WW, ZZ$ minima towards $\xi = 0.162$ with increasing $m_1^g$. Left: $m_1^g = 3$ TeV. Right: $m_1^g = 5$ TeV. The maximal $\gamma\gamma$ rate is achieved for an intermediate value of $\xi$ between the $WW, ZZ$ minima and the $hh, t\bar{t}, b\bar{b}$ zeroes. Note that the $WW, ZZ$ branching ratios do not vanish because of the extra non-SM tensor structure contributions related the the $W, Z$ residing in the bulk.

A few important points:

- The suppression of all modes aside from $\gamma\gamma$ and $gg$ implies strong production and substantial $\gamma\gamma$ rate, as well as limited constraints from all but the di-jet ($gg$) final state. More later using some benchmark points.
- Clearly there are lots of rate correlations that will allow some intimate tests of the model, including determination of $\Lambda_\phi$ and $m_1^g$.
- In the present one-doublet case, the $h$ is extremely SM-like for the $\xi$ values

---

J. Gunion, CERN, March 22, 2016 15
that give a strong $\gamma\gamma$ signal. But, multi-higgs on the brane is a possibility and then the $h_{125}$ properties can deviate from those of the SM Higgs.

- From the plots of Fig. 6, we see that it is not possible to find a $\xi$ choice such that $\text{BR}(\phi \to \gamma\gamma) > \text{BR}(\phi \to VV)$ for the values of $m^g_1$ that allow $\Lambda_\phi$ such as to fit the data. Still, limits on all these final states from the 8 TeV data are consistent with both $m^g_1 = 3$ TeV and $m^g_1 = 5$ TeV.

- Indeed, we see that there is a rough lower bound on the $VV$ final state branching ratios and so these should appear after sufficient data taking at 13 TeV.

- The total width of the $\phi$ is predicted to be well below 1 GeV in this model. This seems to be preferred by CMS but not by ATLAS.

![Figure 6: The total width of the radion $\Gamma^{\text{tot}}_\phi$, as a function of $\xi$ for $m_h = 125$ GeV, $m_\phi = 750$ GeV, $m^g_1 = 3$ TeV (left) or $m^g_1 = 5$ TeV (right) with different choices of $\Lambda_\phi$.](image-url)
Perhaps most important, the $gg$ final state always has very large branching ratio and should be detectable with future LHC running. Results for $gg \rightarrow \phi \rightarrow gg$ at 13 TeV are given in Fig. 7.

Figure 7: We plot $\sigma(gg \rightarrow \phi \rightarrow gg)$ as function of $\xi$ for $m_h = 125$ GeV, $m_\phi = 750$ GeV and $m_1^g = 3$ TeV, color-coded by $\Lambda_\phi$.

For $\xi$ values in the region around the peak for which the observed di-photon cross section is well described, one finds $1 \text{ pb} \lesssim \sigma(gg \rightarrow \phi \rightarrow gg) \lesssim 3 \text{ pb}$. This is certainly below the $10 \text{ pb}/A$ bound extrapolated (using factor of 5 luminosity scaling) from the Run 1 limits assuming the same amount of integrated luminosity ($20 \text{ fb}^{-1}$).

However, for reasonable acceptance at the 13 TeV Run 2, the ATLAS and CMS collaborations should be able to see the $gg$ signal in the di-photon excess region.
Table 1: Ten benchmark points for the Higgs-radion 750 GeV scenario interpretation of the diphoton excess at the LHC. Below $\Lambda_\phi$ is calculated for a given $m^g_1$ and $k/M_{Pl}$ according to Eq. (8). The dimensions for the dimensionful quantities are as follows: $m^g_1$ [TeV], $\Lambda_\phi$ [TeV], $\Gamma_{\phi}^{\text{tot}}$ [GeV], $\sigma_{gg}(VV, tt, hh)$ [fb] and $\sigma_{gg}$ (di-jet) [pb]. The cross sections are those at $\sqrt{s} = 13$ TeV.

We now summarize important aspects of the BMPs.

- **Point #1** gives the maximal $gg$-induced cross section in the $\phi \rightarrow \gamma\gamma$ (and, simultaneously, $gg$) final state for $m_g^q = 3$ TeV when $k/M_{P1} \leq 2$ is required. As noted above, this corresponds to $\Lambda_\phi = 1.5$ TeV. The maximum occurs at $\xi \sim 0.153$, i.e. part way between the minima for the $WW, ZZ$ final state widths and $\xi \simeq 0.162$ where the $t\bar{t}, b\bar{b}, hh$ final state widths vanish. For this point the $\gamma\gamma$ final state has a cross section of order the central ATLAS value. Cross sections in the $hh, ZZ, WW, t\bar{t}$ final states (in that order) range from $75.2$ fb down to $32.5$ fb, while the $gg$ final state has a cross section of $3.54$ pb.

- **Points #2 — #5** illustrate results for $m_g^q = 5$ TeV. In this case, the maximal $\gamma\gamma$ cross section occurs at $\xi \sim 0.159$ (since the $WW, ZZ$ cross section dips have moved closer to the $\xi \simeq 0.162$ point at which the $t\bar{t}, b\bar{b}, hh$ cross sections are zero). The different points illustrate results obtained for decreasing $k/M_{P1}$ values starting from the largest value allowed ($k/M_{P1} = 3$). $\Lambda_\phi$ ranges from $1.67$ TeV up to $2.78$ GeV, the latter being the value for which $\sigma(gg \rightarrow \phi \rightarrow \gamma\gamma)$ is at the lower edge of the CMS observation. Cross sections are ordered according to $WW > ZZ > \gamma\gamma > hh > t\bar{t}$.

The $\gamma\gamma$ cross section for BMP #2 is actually comparable to the case with $m_g^q = 3$ TeV and $k/M_{P1} = 2$. This is due to the fact that the $\Lambda_\phi$ values
corresponding to points #1 and #2 are very close in size. This is important, since if precision bounds or direct detection bounds push up the limits on $m_1^q$, this model can still reproduce the properties of the observed di-photon resonance at 750 GeV as observed by ATLAS.

- Comparing points #1 and #4 we observe the effects of increasing $m_1^q$ from 3 to 5 TeV, keeping $k/M_{Pl} = 2$ constant (so that $\Lambda_\phi$ increases from 1.5 TeV to 2.5 TeV). As expected, we see a drop in the cross-sections to photons and gluons and in the total width.

- It is important to comment that BMPs #1 — #5 are easily consistent with the LHC 8 TeV data.

- Next, Points #6 and #7 are designed to show the limitation on how large the total width could be when fitting the central $\gamma\gamma$ rate reported by CMS. For the two points considered, we take $m_1^q = 3$ TeV. In these cases, the $\gamma\gamma$ final state cross section is smaller than that for any other final state mode, including the $ZZ$ mode even though in the case of point #6 we have chosen $\xi$ to be close to the $ZZ$ minimum point.

For BMP #6, the total width is increased due to the increased width for the $t\bar{t}$
and $hh$ final states. This is a result of choosing a $\xi$ value that is well below the $\xi = 0.162$ value where the $t\bar{t}$ and $hh$ modes are zero, see Fig. 6.

In the case of BMP #7 we have chosen an even lower value of $\xi$ such that the $WW$ and $ZZ$ modes, as well as the $t\bar{t}$ and $hh$ modes, all have large cross sections. In fact, Point #7 is excluded by existing 8 TeV limits on the $hh$ channel (using a downwards rescaling factor of $\sim 5$ relative to the 13 TeV value given). This point thus illustrates the fact that one cannot describe the di-photon excess without having a total width well below 1 GeV.

- Point #8 is chosen to have a $\Lambda_\phi$ value (1.25 TeV) below our nominal lower limit of 1.5 TeV (which applies if $k/M_{Pl} \leq 2$ and $m_1^g \geq 3$ TeV) in order to illustrate how we can obtain a $\gamma\gamma$ cross section at the upper limit of the ATLAS band. Still higher $\gamma\gamma$ cross sections are, of course, possible by lowering $\Lambda_\phi$ further. However, the $ZZ$ final state cross section for this BMP #8 is already on the edge of the 8 TeV ATLAS exclusion limit (using a downwards rescaling factor of $\sim 5$ relative to the tabulated 13 TeV number).

- Points #9 and #10 are designed to illustrate results for $\xi$ at the exact conformal point, $\xi = 1/6 \approx 0.167$, with $\Lambda_\phi$ chosen so as to give a $\gamma\gamma$ cross section near the center of the ATLAS+CMS band in the cases of $m_1^g = 3$ TeV and 5 TeV,
respectively. The very large $WW$ and $ZZ$ cross sections in the $m_1^g = 3$ TeV case translate to $\sqrt{s} = 8$ TeV cross sections that exceed current limits. At $m_1^g = 5$ TeV, the $WW$ and $ZZ$ cross sections are large, but not in conflict with existing limits, although the $ZZ$ final state prediction for 8 TeV is very close to the ATLAS exclusion limit. Thus, the conformal-limit choice for $\xi$ is viable if $m_1^g$ is large enough and $\Lambda_\phi$ is not much above 1.5 TeV.

Of course, these two points illustrate again the limitations on obtaining a large width for the 750 GeV radion state. In these cases we are making a $\xi$ choice well above the minima of the $ZZ$ and $WW$ final state partial widths, but not so far above the zero of the $hh$ partial width ($\xi = 0.162047$). Therefore (unlike for BMP #7 where the $hh$ width is large) here it is the $ZZ$ and $WW$ final state exclusion limits that restrict our ability to get a total width that is more than a fraction of a GeV.

Conclusions

- The Higgs responsible for EWSB has emerged and is really very SM-like.

- RS avoids hierarchy problem and so maybe no supersymmetry. RS requires a radion, the quantum fluctuation association with brane separation.

- Have we seen the radion at 750 GeV? It is very consistent with what is seen in the $\gamma\gamma$ mode and absence (so far) of other modes if $\Lambda_{\phi} \lesssim 2.5$ TeV.

- RS scenario can be extended by allowing more complicated Higgs sector on the brane. Thus, there is no reason not to have additional Higgs bosons.

   One can just add to the Higgs sector of the model with impunity so long as the TeV brane multi-higgs model parameters are chosen so that we are in the alignment limit for whatever Higgs boson has mass of 125 GeV.

   Of course, the $g_{\phi} \sim 0$ limit is needed to prevent dilution of the $\phi \rightarrow \gamma\gamma$ signal rate.

   We must continue to push hard to improve limits/sensitivity to additional Higgs bosons.
Higgs could be everything, even providing the dark matter.

This is much easier/less-constrained in the 2HDM + Singlet context than in the SM + Singlet context because either $h$ or $H$ can be the SM-like Higgs at 125 GeV while the other, $H$ or $h$, respectively, can mediate dark matter annihilation.
